

## Temperature, Heat, & Expansion

## Temperature

- Atoms and molecules are constantly in motion, and *temperature* is related to the average kinetic energy of these molecules.
- The more the molecules move, the greater their KE, and the greater the temperature of the object.
- Temperature IS NOT the energy of the object. It's *related to* the energy of the object.

## Thermometers

- ...measure temperature.
- There are three common temperature scales.
  - *Fahrenheit*
  - *Celsius* (formerly "Centigrade")
  - *Kelvin*

## Temperature Scales

$$^{\circ}\text{C} = \frac{5}{9} (^{\circ}\text{F} - 32)$$

$$\text{K} = ^{\circ}\text{C} + 273.15$$

## Heat

*Heat* is simply the transfer of energy from one body to another. We can call the type of energy being transferred *thermal energy*, but it's more appropriate to call it a *change in internal energy* (because it is related to the changing internal kinetic energy of the moving molecules in a substance).

When two substances of different temperatures are brought into contact with each other, energy (in the form of "heat") spontaneously flows from the warmer body to the cooler body.

## Thermal Equilibrium

As you might expect, this can't go on forever.

Eventually, the two bodies reach the same temperature, at which point they are in *thermal equilibrium*.

### How is heat (energy flow) measured?

$$Q = mC\Delta T$$

$Q$  = heat (in Joules or calories, depending)

$m$  = mass of material being heated or cooled (in g, usually)

$C$  = specific heat capacity

$\Delta T$  = change in temperature ( $^{\circ}\text{C}$ )

$C$  for water = 1 calorie/ $g^{\circ}\text{C}$

$C$  for water = 4.184 J/ $g^{\circ}\text{C}$

1 calorie = 4.184 J

### What is “specific heat capacity”?

$$Q = mC\Delta T$$

How much energy will it take to heat 100g of water up by  $10^{\circ}\text{C}$ ?

How much energy will it take to heat 100g of iron up by  $10^{\circ}\text{C}$ ? ( $C_{\text{iron}}=0.107 \text{ cal / g}^{\circ}\text{C}$ )

We say that iron has a lower heat capacity than water, because it takes less energy to change its temperature.

### Example-1

How much heat is necessary to raise the temperature of 50 g of a metal from  $20.0^{\circ}\text{C}$  (room temperature) to  $50.0^{\circ}\text{C}$  if the specific heat capacity for the metal is  $0.4 \text{ cal / g }^{\circ}\text{C}$ ?

### Example-2

What is the final temperature of 300 ml of water, if it starts out at boiling ( $100^{\circ}\text{C}$ ), and has  $3.77\text{e}4$  Joules of energy taken away?

### Example-3

500 ml of water at  $20.0^{\circ}\text{C}$  is mixed with hot water at  $70.0^{\circ}\text{C}$  to produce water with a final temperature of  $50.0^{\circ}\text{C}$ . How much hot water was there?

### Example-4

What is the final (equilibrium) temperature of 20g of iron at  $300^{\circ}\text{C}$  dropped in a 2-liter bottle of water at  $70^{\circ}\text{F}$ ?
